[12,3,4] *Department of Mechanical Engineering, Kyushu Institute of Technology, Japan*

Abstract: In this paper interfacial edge crack problems are considered by the application of the finite element method. The stress intensity factors are accurately determined from the ratio of crack-tip-stress value between the target given unknown and reference problems. The reference problem is chosen to produce the singular stress fields proportional to the ones of the given unknown problem. Here the original proportional method is improved through utilizing very refined meshes and post-processing technique of linear extrapolation. The results for a double-edge interface crack in a bonded strip are newly obtained and compared with the ones of a single-edge interface crack for various material combinations. It is found that the stress intensity factors should be compared in the three different zones of relative crack lengths. Differently from the case of a cracked homogenous strip, the results for the double edge interface cracks are found to possibly be bigger than those for a single edge interface crack under the same relative crack length.

Key Words : *Stress intensity factor; Single Edge interface crack; Double edge interface crack; Material combination; Bonded strip.*

1. Introduction

Composite materials and bonded structures are widely employed in the modern industrial context. The

mechanical behavior of the bi-material interface is of great significance for the industrial application. Since the presence of cracks negatively affects a structure's performance and may result in damage, basic studies about the interface cracks win quite a number of attentions. High stress concentration at the bonding edge corner caused by differences in the elastic properties of its material components may lead to the initiation of micro-cracks and then to the propagation. Therefore, the single and double edge interface cracks will be mainly investigated in this research.

The asymptotic solutions of the singular stress field near the interface corner have been well solved till recently [1-9]. However, multiple/oscillatory singularity adds to the hardship of determination of the stress intensity factors of the interfacial cracks. Till recently, various numerical methods have been reported to determine the stress intensity factors of an interface crack. Specifically, Wu [10] presented for calculating the stress intensity factors at the tip of an interface crack based on an evaluation of the J-integral by the virtual crack extension method. Yang ang Kuang [11] established a path independent contour integral method for the stress intensity factors of the interface crack. Munz and Yang[12] used the FE-method to analyze the stress singularities at the interface for a rectangular bi-material bonded plate subjected to two loading conditions. Dong et al. [13] proposed procedures for stress intensity factor computation using traction singular quarter-point boundary elements. Liu [14] et al. developed a simple and effective numerical method to calculate the stress intensity factors for an interface crack with one or two singularities. Oda et al. [15] extended the crack tip method [16] into solving the interface crack problems by using the ratio of crack-tip-stress value between the given unknown and reference problems. Here, the reference problem is chosen to produce the singular stress fields

proportional to the ones of given unknown problem.

In the authors' previous research, Noda et al. investigated the stress intensity factors of an edge interface crack in a bonded dissimilar semi-infinite plane [17]. Then Lan et al. discussed the effect of the material combinations and the relative crack lengths to the stress intensity factors of a single edge cracked bonded strip [18]. As a further research of the authors' previous work, the study object is extended to the double edge interface crack of a bonded strip. In this paper the stress intensity factors for a bi-material bonded strip with single and double edge interface cracks as shown in Fig.1a and b will be examined using the improved proportional method. The stress intensity factors will be computed and listed by varying various material combinations and relative crack lengths. Then the values for the two different types of cracks will be compared for the whole range of combination of materials ($0 \le \alpha \le 0.95, -0.2 \le \beta \le 0.45$) and relative crack lengths ($0 \le a/W \le 0.9$).The effect of the relative crack lengths and material mismatch parameters are of special interest in this paper. It will be shown that the stress intensity factors of a double edge interface crack may be possibly larger than those of a single edge interface crack for some specific combination of materials and relative crack lengths differently from the case of a cracked homogenous strip.

Fig. 1 (a)(b)(c)

2. Analysis Method

2.1 Physical background

Recently, an effective method was proposed for computing the stress intensity factors in a cracked homogenous plate [16]. Then, the method was successfully extended to the interfacial crack problems [15]. Both of those methods utilize the stress component values at the crack tip computed by FEM. For a given bi-material bonded structure, the stress intensity factors are defined as shown in Eq. (1) [19].

$$\sigma_y + i\tau_{xy} = \frac{K_I + iK_{II}}{\sqrt{2\pi r}}\left(\frac{r}{2a}\right)^{i\varepsilon}, r \to 0 \tag{1}$$

Here, σ_y, τ_{xy} denote the stress components near the crack tip. r is the radial distance from the crack tip, and ε is the bi-elastic constant given by:

$$\varepsilon = \frac{1}{2\pi}\ln\left[\left(\frac{\kappa_1}{G_1}+\frac{1}{G_2}\right)/\left(\frac{\kappa_2}{G_2}+\frac{1}{G_1}\right)\right] \tag{2}$$

$$\kappa_m = \begin{cases} 3-4\nu_m \ (plane \quad strain) \\ 3-\nu_m/1+\nu_m \ (plane \quad stress) \end{cases}, \quad (m=1,2) \tag{3}$$

Where $G_m\,(m=1,2)$ and $\nu_m\,(m=1,2)$ are the shear moduli and poisson's ratios of either respective materials. The real and imaginary parts of the oscillatory stress intensity factors $K_I + iK_{II}$ in Eq.(1) may be separated as

$$K_I = \lim_{r\to 0}\sqrt{2\pi r}\sigma_y\left(\cos Q + \frac{\tau_{xy}}{\sigma_y}\sin Q\right) \tag{4}$$

$$K_{II} = \lim_{r\to 0}\sqrt{2\pi r}\tau_{xy}\left(\cos Q - \frac{\sigma_y}{\tau_{xy}}\sin Q\right) \tag{5}$$

$$Q = \varepsilon\ln(\frac{r}{2a}) \tag{6}$$

For the two interface crack problems C and D shown in Fig. 2a and b. Assuming they have the same crack lengths (half length) $a = a_0$ and the same combination of materials $\varepsilon = \varepsilon_0$. Examining the points along the interface with the same radial distances $r = r_0$ for the two problems C and D, then gives $\left[Q^*\right]_C = \left[Q\right]_D = \varepsilon_0\ln(\frac{r_0}{2a_0})$. Recall Eq.(4) and (5), a proportional relationship given in Eq.(7) is established

if and only if Eq.(8) can be satisfied,

$$\frac{\left[K_I\right]_D}{\left[K_I^*\right]_C}=\frac{\left[\sigma_y\right]_D}{\left[\sigma_y^*\right]_C}=\frac{\left[\sigma_{y0,FEM}\right]_D}{\left[\sigma_{y0,FEM}^*\right]_C},\frac{\left[K_{II}\right]_D}{\left[K_{II}^*\right]_C}=\frac{\left[\tau_{xy}\right]_D}{\left[\tau_{xy}^*\right]_C}=\frac{\left[\tau_{xy0,FEM}\right]_D}{\left[\tau_{xy0,FEM}^*\right]_C} \tag{7}$$

$$\left[\frac{\tau_{xy}^*}{\sigma_y^*}\right]_C=\left[\frac{\tau_{xy}}{\sigma_y}\right]_D,\left[\frac{\tau_{xy0,FEM}\,*}{\sigma_{y0,FEM}\,*}\right]_C=\left[\frac{\tau_{xy0,FEM}}{\sigma_{y0,FEM}}\right]_D \tag{8}$$

Assuming the stress intensity factors of problem C are given in advance and denote problem C as the reference problem, those of problem D are unknown and left to be solved(the target unknown problem). Rearranging Eq.(7) gives the stress intensity factors of the target unknown problem (problem D) as:

$$\left[K_I\right]_D=\frac{\left[\sigma_{y0,FEM}\right]_D\left[K_I^*\right]_C}{\left[\sigma_{y0,FEM}^*\right]_C},\left[K_{II}\right]_D=\frac{\left[\tau_{xy0,FEM}\right]_D\left[K_{II}^*\right]_C}{\left[\tau_{xy0,FEM}^*\right]_C} \tag{9}$$

Here, $\sigma_{y0,FEM}^*,\tau_{xy0,FEM}^*$ and $\sigma_{y0,FEM},\tau_{xy0,FEM}$ are the stress components at the crack tip computed by FEM of the reference and target unknown problems respectively.

2.2 Determination of the reference problems

In this study, a central cracked bonded dissimilar half-plane subjected to remote uniform tension $\sigma_y^\infty=T$ and $\tau_{xy}^\infty=S$ as shown in Fig. 2a is treated as the reference problem. And its stress intensity factors are given by the theoretical solution as

$$K_I^*+iK_{II}^*=(\sigma_y^\infty+i\tau_{xy}^\infty)\sqrt{\pi a}(1+2i\varepsilon),\quad \sigma_y^\infty=T,\tau_{xy}^\infty=S \tag{10}$$

Let $\sigma_{y0,FEM}^{T=1,S=0}*,\tau_{xy0,FEM}^{T=1,S=0}*$ and $\sigma_{y0,FEM}^{T=0,S=1}*,\tau_{xy0,FEM}^{T=0,S=1}*$ denote the stress components of the bonded dissimilar half-plane shown in Fig. 2a subjected to pure remote tension $(T,S)=(1,0)$ and pure remote shear $(T,S)=(0,1)$, respectively. Then, using the principle of superposition, the stress components of the reference problem shown in Fig. 2a take the following form:

$$\sigma_{y0,FEM}^{*} = \sigma_{y0,FEM}^{T=1,S=0} * \times T + \sigma_{y0,FEM}^{T=0,S=1} * \times S \tag{11}$$

$$\tau_{xy0,FEM}^{*} = \tau_{xy0,FEM}^{T=1,S=0} * \times T + \tau_{xy0,FEM}^{T=0,S=1} * \times S \tag{12}$$

As aforementioned, the condition given in Eq.(8) needs to be satisfied. Inserting Eq.(11),(12) into Eq.(8) gives the solution of S/T for determining the remote external loads applied to the reference problem.

$$\frac{S}{T} = \frac{\left[\sigma_{y0,FEM}\right]_D \times \left[\tau_{xy0,FEM}^{T=1,S=0} *\right]_C - \left[\tau_{xy0,FEM}\right]_D \times \left[\sigma_{y0,FEM}^{T=1,S=0} *\right]_C}{\left[\tau_{xy0,FEM}\right]_D \times \left[\sigma_{y0,FEM}^{T=0,S=1} *\right]_C - \left[\sigma_{y0,FEM}\right]_D \times \left[\tau_{xy0,FEM}^{T=0,S=1} *\right]_C} \tag{13}$$

When the external load for the reference problem (problem C) $\sigma_y^{\infty}=T$ and $\tau_{xy}^{\infty}=S$ can satisfy Eq.(13), Eq.(9) can be satisfied. Specifically, let $T=1$ so that S can be determined. Inserting $T=1,S$ into Eq.(10) gives the exact values of the oscillatory stress intensity factors for the reference problem (problem C). Finally, the stress intensity factors for the target unknown problem (problem D) can be yielded using the proportional relationship as given in Eq.(9). Furthermore, the oscillatory terms in the above discussion will vanish when the two materials are identical, so the current method is also available to the cracked homogenous plate problems.

Fig. 2 (a)(b) +Fig.3

3. Numerical results and discussion

3.1 Formulation of the single and double edge interface crack problems for arbitrary material combinations

Regarding the bonded strip of width W and length L shown in Fig. 1a,b and c, the length L of the strip is assumed to be much greater than the width W ($L \geq 2W$). It is composed of two elastic, isotropic and homogeneous strips that are perfectly bonded along the interface. And the strip is

subjected to a remote uniform tensile stress σ. The material above the interface is termed material 1, and the material below is termed material 2. Consider the bi-material bonded plate shown in Fig.1c. It is supposed that a single edge crack shown in Fig.1a and a double one shown in Fig.1b with a crack length of a have initiated at the free edge corner of the bonded plate.

The stress intensity factors for the aforementioned problems in plane strain or plane stress are only determined on the two elastic mismatch parameters α and β (also known as *Dundurs' material composite parameters*, Dundurs, 1969). And the Dundurs' material composite parameters are defined as

$$\alpha = \frac{G_1(\kappa_2+1)-G_2(\kappa_1+1)}{G_1(\kappa_2+1)+G_2(\kappa_1+1)}, \beta = \frac{G_1(\kappa_2-1)-G_2(\kappa_1-1)}{G_1(\kappa_2+1)+G_2(\kappa_1+1)} \tag{14}$$

where, the subscripts denote material 1 or 2, $G_m = E_m/2(1+\nu_m), (m=1,2)$, G_m, E_m and ν_m denote shear modulus, Young's modulus and Poisson's ratio for material m, respectively. $\kappa_m = (3-\nu_m)/(1+\nu_m)$ for plane stress and $\kappa_m = (3-4\nu_m)$ for plane strain. The parameter α is positive when material 2 is more compliant than material 1, and is negative when material 2 is stiffer than material 1. In this research, only the stress intensity factors for $\beta \geq 0$ in $\alpha - \beta$ space shown in Fig.3 has been investigated since switching material 1 and 2 ($mat1 \Leftrightarrow mat2$)will only reverse the signs of α and β ($(\alpha,\beta) \Leftrightarrow (-\alpha,-\beta)$). Furthermore, in order to make the discussion convenient, all the stress intensity factors are normalized using the following equations:

$$F_I = K_I/\left(\sigma\sqrt{\pi a}\right), F_{II} = K_{II}/\left(\sigma\sqrt{\pi a}\right) \tag{15}$$

Fig. 4 + Fig.5(a)(b) +Fig.6(a)(b)	Table 1 + Table 2 + Table 3

3.2 Numerical verification for the single and double edge crack problems

The robustness and accuracy of the current method in treating the single and double edge cracked problems are investigated. MSC.MARC 2007 r1 finite element analysis package is used in this research. Four-node quadrilateral elements are employed to mesh the reference and the target unknown problems. Fig.4 shows the FE mesh type for a single-edge cracked homogenous strip (target unknown problem). As can be seen from this figure, the meshes within the vicinity of the singular zone are subdivided in a self-similar manner. And the element size for each inferior layer is one third of that of the superior one.

The stress intensity factors for the extremely deep crack cases ($a/W = 0.8$) of a single and a double edge cracked homogenous strips are plotted against the minimum element size of the FE model in Fig.5a and b, respectively. As can be seen from the figures, accurate results can be obtained using linear extrapolation. The values for other relative crack lengths of the two types of cracks are tabulated and compared to those predicted by Kaya [20], Noda [21] and Nisitani [22] in Table 1, respectively. It can be seen from the table that the extrapolated results in this research and those of Kaya [20], Noda [21] and Nisitani [22] are in very good agreement.

Fig.6a and b show the variations of the normalized stress intensity factors $F_I = K_I/\sigma\sqrt{\pi a}$ and $F_{II} = K_{II}/\sigma\sqrt{\pi a}$ for a single edge cracked dissimilar bonded strip $a/W = 0.8$. The elastic parameters are restricted to $G_2/G_1 = 4, \nu_2 = \nu_1 = 0.3$ and plane stress condition is assumed in the analysis. As can be seen

from Fig.6a, a linear relationship can be observed for the case of $K_I/\sigma\sqrt{\pi a}$. However, a simple linear behavior is not observed for the case of $K_{II}/\sigma\sqrt{\pi a}$ in Fig.6b. It should be noted that a post-processing technique of linear extrapolation is used to compute both the values of $F_I = K_I/\sigma\sqrt{\pi a}$ and $F_{II} = K_{II}/\sigma\sqrt{\pi a}$ in this research. The extrapolated values of other relative crack lengths are tabulated in Table 2 together with those of Matsumto[23], Yuuki [24] and Ikeda [25]. Table 2 illustrates that the stress intensity factor values computed by the current method are in very good agreement with those predicted by Matsumto[23] , Yuuki[24] and Ikeda[25]. And the worst computational errors relative to those of Ikeda are $error\left(K_1/\sigma\sqrt{\pi a}\right) = 0.13\%$ and $error\left(K_2/\sigma\sqrt{\pi a}\right) = 0.03\%$ for the deep edge crack case $a/W = 0.8$.

The stress intensity factors for a double edge cracked bonded strip shown in Fig.1b are tabulated in Table 3. Linear extrapolation is also employed for this case. Those results in Table 3 are new and there are no published data to be compared with them. As shown in the previous examples, the current method is found to produce accurate numerical values for mode I cracks; and therefore, Table 3 is also reliable.

Fig. 7 + Fig.8(a)(b)

3.3 Stress intensity factors for the single and double edge interface cracks in a bonded strip

In this section, the stress intensity factors at the crack tip for a double edge interface crack in a bi-material bonded strip are systematically investigated for various material combinations and crack lengths. For the case of a single and a double edge cracked homogenous strips shown in Fig.7, it is well known that the stress intensity factors for the single crack are always no less than those of the double

crack. However, this law should not be always true for the case of interfacial cracks. The stress intensity factors for the single and double edge interface cracks will be compared for arbitrary combination of materials in the following section.

3.2.1 Stress intensity factors for the double edge interface cracks within the zone of free-edge singularity

In the authors' previous research, it has been confirmed that the normalized stress intensity factors within the zone of free-edge singularity for a single edge cracked bonded strip behave a linear double logarithmic relationship with the relative crack length a/W [17]. Here, the double edge interface cracks are the main interests. The stress intensity factors will be investigated by varying the relative crack length a/W, as well as the material composite parameters α and β. Then the stress intensity factors for those two interfacial cracks will be compared systematically. We restrict our discussion to the material combinations with $\beta = 0.3$, and the same phenomenon can be found from others material combinations. The double logarithmic distributions of the normalized stress intensity factors F_I and F_{II} for the single and double edge interface cracks are plotted against a/W as shown in Fig. 8a and b, respectively. The values of F_I, F_{II} for the double edge interface cracks are plotted in solid curves and those for the single edge interface cracks are plotted in dashed ones. From Fig.8, it can be found that, similar as the case of the single edge interface crack, the double logarithmic distributions of F_I, F_{II} for a double-edge cracked bonded strip also behave linearity when $a/W < 0.01$. Furthermore, the slopes corresponding to the same material composite parameters for the two crack cases are totally same, and they are equal to the singular index $\lambda - 1$ of the perfectly bonded strip without crack as

shown in Fig.1c. This proves that the singular zone for a shallow edge interface crack is controlled by the stress state near the interface corner of the corresponding un-cracked bonded strip. Recently the singular field at the interface corner for a bonded strip as shown in Fig.9a has been studied in several publications [1-9]. If an interface crack is introduced as shown in Fig. 9b, the stress intensity factors are controlled by the stress states near the corner which the free edge intersects with the interface.

Fig. 9(a)(b)

The double logarithmic discussions about the case of a single edge interface crack in Ref.[17] are also applicable to the case of a double edge interface crack. An empirical function as Eq.(16) was proposed to compute F_I, F_{II} of a single edge interface crack within the singular zone of a bonded strip [17]. Where, F_I, F_{II} are the normalized stress intensity factors, a/W is the relative crack length, $1-\lambda$ is the order of stress singularity for the perfectly bonded strip without crack and C_I, C_{II} are constants determined by the material composite parameters and crack type. It has been proved that Eq.(16) is also suitable for the double edge crack case by modifying the constants C_I, C_{II}. Here, what should be noticed is that F_I, F_{II} are the same within the singular zone for the two types of cracks when $\alpha(\alpha - 2\beta) = 0$ (see, the curve of $\alpha = 0.6, \beta = 0.3, a/W < 0.01$ in Fig.8). The detailed information can be referred in Ref.[17].

$$F_I \cdot (a/W)^{1-\lambda} = C_I, F_{II} \cdot (a/W)^{1-\lambda} = C_{II} \tag{16}$$

For the bonded strip without crack as shown in Fig. 9a, the values of λ can be obtained by solving the following eigen equation [3][26].

$$\begin{aligned} \mathbf{D}(\alpha,\beta,\lambda) = &\left[\cos^2\left(\frac{\pi}{2}\lambda\right) - (1-\lambda)^2\right]^2 \beta^2 + 2(1-\lambda)^2\left[\cos^2\left(\frac{\pi}{2}\lambda\right) - (1-\lambda)^2\right]\alpha\beta \\ &+ (1-\lambda)^2\left[(1-\lambda)^2 - 1\right]\alpha^2 + \cos^2\left(\frac{\lambda\pi}{2}\right)\sin^2\left(\frac{\lambda\pi}{2}\right) = 0 \end{aligned} \tag{17}$$

Where, when singularity exists near the interface corner, λ is the zero of $\mathbf{D}(\alpha,\beta,\lambda)$ in $0<\mathrm{Re}(\lambda)<1$ that has the smallest real part. In general, $\mathbf{D}(\alpha,\beta,\lambda)$ is expected to have several zeros in $0<\mathrm{Re}(\lambda)<1$. In all cases where more than one zero of $\mathbf{D}(\alpha,\beta,\lambda)$ occurs only the smallest one will be exhibited (Bogy, 1971) [3]. The values of λ are computed for arbitrary material composite parameters (α,β) in the authors' previous research [17].

The constants C_I, C_{II} in Eq.(16) for the double edge crack case are computed for various material composite parameters. The values of C_I, C_{II} are plotted and tabulated against (α,β) in Fig.10a and b as well as in Table 4 and Table 5, respectively.

Fig. 10(a)(b) + Table 4 + Table 5

Recall Eq.(16) and Fig.10, the stress intensity factors at the crack tip for the two types of cracks with the same relative crack length a/W within the singular zone of a bonded strip (shallow crack, $a/W<0.01$) have the following relationships.

$F_{I,Dbl}>F_{I,Sgl}, F_{II,Dbl}>F_{II,Sgl}$, when $\alpha(\alpha-2\beta)>0$;

$F_{I,Dbl}=F_{I,Sgl}, F_{II,Dbl}=F_{II,Sgl}$, when $\alpha(\alpha-2\beta)=0$;

$F_{I,Dbl}<F_{I,Sgl}, F_{II,Dbl}<F_{II,Sgl}$, when $\alpha(\alpha-2\beta)<0$.

Where, $F_{I,Dbl}, F_{II,Dbl}$ denote the normalized stress intensity factors within the singular zone for a double edge interface crack, and $F_{I,Sgl}, F_{II,Sgl}$ denote those for a single edge interface crack.

The size of the zone of dominance of free-edge singularity can be determined in a manner as given below. The double logarithmic lines for the single and double edge interface cracks under the same

material parameters should be parallel (the line slopes are equal to the order of stress singularity $1-\lambda$). Then, by examining the agreement of the slopes of the double logarithmic lines of F_I, F_{II} for the two cases with the theoretical values of $1-\lambda$ computed by Eq.(17) , the size of the singular zone can be determined. Take $\beta = 0.3$ as an example, extremely good agreement for the two slopes can be found for $a/W < 0.001$ and an error within 5% for $a/W < 0.01$. So, the size of singular zone can be roughly decided as $a/W < 0.01$. The singular zone along the interface in this paper almost agrees with that obtained by Reedy (1993) for an in infinitely long biomaterial bonded strip under tension $(\alpha = -0.8, \beta = 0)$ [27]. More computations of the stress intensity factors for $0.001 < a/W < 0.01$ are needed to determine the size of the singular zone accurately.

Fig. 11(a)(b) + Fig. 12(a)(b) + Fig. 13(a)(b)

3.2.2 Stress intensity factors for double edge interface cracks outside the zone of free-edge singularity

The normalized stress intensity factor curves of three typical material combinations shown in Fig.8 are chosen and plotted in Fig.11. As can be seen from the figure, the whole transverse region of the bonded strip shown in Fig. 1c can be separated into three different zones. Namely, they are denoted as zone 1, 2 and 3 as shown in Fig.11 for notational convenient. The boundaries of zone 1 and 2 as well as zone 2 and 3 are roughly defined as $0.01W$ and $0.1W$ respectively. Zone 1 is termed the zone of dominance of free-edge singularity, and it has been discussed in Section 3.2.1. If the crack length is located in zone 1 ($a/W \le 0.01$),the stress intensity factors for the two types of cracks can be obtained by Eq.(16). Zone 2 is regarded as the transitional zone between zone 1 and 3. As can be seen from Fig.11,

the stress intensity factors of a single edge interface crack within zone 3 are always bigger than those of a double edge interface crack. This phenomenon is caused by the counterbalance effect of the symmetry of the double edge interface crack. However, when the crack is located in zone 2 (say, $0.01 \le a/W \le 0.1$), the relationships of the stress intensity factors for the two types of cracks become complexity, and no unique or clear regular pattern can be followed. In this case, the stress intensity factors are determined by the combined effect of the free-edge singularity and the symmetrical counterbalance. Generally, the left part of zone 2 is mainly affected by the free-edge singularity and the right part is dominated by the counterbalance effect. Specifically, F_I, F_{II} for $a/W = 0.1$ (zone 2) are plotted against various combination of materials in Fig.12a and b respectively. It can be seen clearly that the stress intensity factors for a double edge interface crack can still be bigger than those of a single edge crack for specific combination of materials. Fig.13a and b show the variations of F_I, F_{II} for $a/W = 0.2$ (zone 3) for various combination of materials respectively. Fig. 13a and b show that the absolute values of F_I, F_{II} for a single edge crack are always bigger than those of a double edge crack.

4. Conclusions

The stress intensity factors can be evaluated by using the ratio of numerical solutions of the stress components computed by an ordinary numerical code (see, FEM) for the reference and the target unknown problems. In this paper, variations of the normalized stress intensity factors F_I, F_{II} at the crack tip of the single and double edge interface cracks in a bi-material bonded strip were investigated and indicated for various material combinations and relative crack lengths a/W. Then, those for the

two types of cracks were systematically compared. It was found in this research, that the stress intensity factors for the double edge interface crack also behave a similar double logarithmic relationship as those of the single edge interface crack. Furthermore, the values of the double edge interface cracks can also be bigger than those of the single edge interface cracks.
